Stochastic Gravitational Wave Measurements with Bar Detectors:
Dependence of Response on Detector Orientation

(Dated: September 27, 2005)

Abstract

The response of a cross-correlation measurement to an isotropic stochastic gravitational-wave background depends on the observing geometry via the overlap reduction function. If one of the detectors being correlated is a resonant bar whose orientation can be changed, the response to stochastic gravitational waves can be modulated. I derive the general form of this modulation as a function of azimuth, both in the zero-frequency limit and at arbitrary frequencies. Comparisons are made between pairs of nearby detectors, such as LIGO Livingston-ALLEGRO, Virgo-AURIGA, Virgo-NAUTILUS, and EXPLORER-AURIGA, with which stochastic cross-correlation measurements are currently being performed, planned, or considered.

I. BACKGROUND AND MOTIVATION

A. Stochastic Backgrounds and Cross-Correlation Measurements

One of the gravitational wave (GW) sources targeted by the current generation of ground-based interferometric and resonant detectors is a stochastic GW background (SGWB), produced by an unresolved superposition of signals of astrophysical or cosmological origin. Direct measurements can be made of, or observational limits set on, a SGWB by looking for correlations in the outputs of a pair of GW detectors.

The response of a pair of detectors to a SGWB depends in part on the observing geometry, in the form of the relative orientation and separation of the two detectors. If one or both of the detectors is a resonant bar detector, its orientation can conceivably be changed, thereby altering the observing geometry and the response of the cross-correlation experiment to a stochastic GW background. For example, the experimental setup of the ALLEGRO resonant bar detector allows for rotation of the detector. This produces a modulation of in the stochastic GW response which is used in the cross-correlation measurements being conducted between ALLEGRO and the interferometer (IFO) at the LIGO Livingston Observatory (LLO).

In the case of LLO and ALLEGRO, where the separation between the detectors (about 40 km) is small compared to the wavelength of gravitational waves to which both detectors are sensitive (about 300 km), the azimuth dependence of the response is very nearly the same as for colocated detectors: sinusoidal with a period of $180^\circ$. This work considers analytically the general dependence of the stochastic gravitational-wave response on the orientation of a bar detector, and applies the results to existing pairs of detectors.

B. Mathematical Details

If a SGWB is isotropic, unpolarized, Gaussian, and stationary, it is completely described by its power spectrum. It is conventional to express this spectrum in terms of the GW contribution to the cosmological parameter $\Omega = \rho/\rho_{\text{crit}}$:

$$\Omega_{\text{GW}}(f) = \frac{1}{\rho_{\text{crit}}} \frac{d\rho_{\text{GW}}}{d\ln f} = \frac{f}{\rho_{\text{crit}}} \frac{d\rho_{\text{GW}}}{df}. \quad (1.1)$$
If \( \tilde{h}_{1,2}(f) \) are the Fourier transforms of the detector outputs, the correlation in the presence of a SGWB of spectrum \( \Omega(f) \) should be

\[
\langle \tilde{h}_1(f) \ast \tilde{h}_2(f') \rangle = \frac{3H_0^2}{20\pi^2} \delta(f - f') \gamma(|f|) \Omega_{GW}(|f|)
\]

(1.2)

where \( \gamma(f) \) is a geometrical factor involving the location and orientation of the two detectors, which we describe in detail in Section II. This factor also appears in the sensitivity of a standard cross-correlation technique, for example in the case of a background whose \( \Omega_{GW}(f) \) is constant over the frequency band of interest:

\[
\Omega_{sens} \sim \left( T \int df \frac{\gamma^2(f)}{f^6 P_1(f) P_2(f)} \right)^{-1/2}.
\]

(1.3)

II. DEFINITION OF THE OVERLAP REDUCTION FUNCTION

The factor \( \gamma(f) \) appearing in (1.2) and (1.3) is typically (see e.g., [2]) defined as

\[
\gamma(f) = \frac{5}{8\pi} \sum_{A=+,-} \int d\Omega_\hat{n} F_{1A}(\hat{n}) F_{2A}(\hat{n}) e^{i2\pi f_{\hat{n}} \cdot (\vec{r}_2 - \vec{r}_1)/c}
\]

(2.1)

where \( \vec{r}_1 \) and \( \vec{r}_2 \) are the positions of the two detectors, and \( F_{1A}(\hat{n}) \) and \( F_{2A}(\hat{n}) \) are their beam patterns. We follow the lead of [10] by factoring the response tensors (cf. Appendix A) out of the integral and writing

\[
\gamma(f) = d_{1ab} \Gamma_{cd}^{ab}(\alpha, \hat{s}) d_{2cd}
\]

(2.2)

where

\[
\hat{s} = \frac{\vec{r}_1 - \vec{r}_2}{|\vec{r}_1 - \vec{r}_2|}
\]

(2.3)

is the unit vector pointing from one detector to the other, and

\[
\alpha = \frac{2\pi f |\vec{r}_1 - \vec{r}_2|}{c}
\]

(2.4)

By using the definition of the transverse, traceless projector in (A3), we note that we can write

\[
\Gamma_{cd}^{ab}(\alpha, \hat{s}) = \frac{5}{4\pi} \int d^2 \Omega_\hat{n} P_{TT}^{ab} \delta_{cd} e^{i\alpha \hat{n} \cdot \hat{s}}
\]

(2.5)

Note that this gives an alternate definition of the overlap reduction function which is manifestly independent of any polarization basis:

\[
\gamma(f) = d_{1ab} d_{2cd} \frac{5}{4\pi} \int d^2 \Omega_\hat{n} P_{TT}^{ab} \delta_{cd} e^{i2\pi f_{\hat{n}} \cdot (\vec{r}_2 - \vec{r}_1)/c}
\]

(2.6)
Written in the form (2.5), it is clear that $\Gamma^{ab}_{cd}(\alpha, \hat{s})$ is symmetric and traceless on both pairs of indices ($\{ab\}$ and $\{cd\}$). With $\hat{s}$ as the only preferred direction, there are only three independent tensors which can be created with these properties:

\[
T^{ab}_{1cd} = P^{ab}_{cd} \\
T^{ab}_{2cd}(\hat{s}) = P^{ab}_{ef} \hat{s}^e \hat{s}^f P^{ef}_{cd} \\
T^{ab}_{3cd}(\hat{s}) = P^{ab}_{ef} \hat{s}^e \hat{s}^f \hat{s}_g \hat{s}_h P^{gh}_{cd}
\]

(Previous derivations \[2, 10\] included two additional terms which were not traceless, the coefficients of which are of course zero.) The most general possible form is thus

\[
\Gamma^{ab}_{cd}(\alpha, \hat{s}) = \sum_{n=1}^{3} \rho_n(\alpha) T^{ab}_{ncd}
\]

and hence

\[
\gamma(f) = \rho_1(\alpha) d^T_{1ab} d^T_{2ab} + \rho_2(\alpha) d^T_{1ab} \hat{s}_b \hat{s}_c d^T_{2ac} + \rho_3(\alpha) d^T_{1ab} \hat{s}_a \hat{s}_b \hat{s}_c \hat{s}_d d^T_{2cd}
\]

The complete functional forms of the coefficients are derived in \[10\] and corrected in \[2, 12\], and a slightly simplified derivation appears in Appendix \[B\] of the present paper. First, however, it is elucidating to note the behavior at $\alpha = 0$, which corresponds either to the low-frequency limit or to the case where the two detectors are co-located. In that case, (2.5) becomes

\[
\Gamma^{ab}_{cd}(0, \hat{s}) = \frac{5}{4\pi} \int \int d^2 \Omega_{\hat{n}} P^{TTab}_{nab} \]

which is manifestly independent of the separation direction $\hat{s}$. That tells us that it can contain only the $\hat{s}$-independent term $T^{ab}_{1cd}$. I.e., $\rho_2(0) = 0 = \rho_3(0)$, leaving

\[
\Gamma^{ab}_{cd}(0, \hat{s}) = \rho_1(0) P^{Ttab}_{cd} = \frac{5}{4\pi} \int \int d^2 \Omega_{\hat{n}} P^{TTab}_{nab}
\]

It’s easy to solve for $\rho_1(0)$ by taking the trace of (2.11) and using (A5) and (A6) to say

\[
\Gamma^{ab}_{ab}(0, \hat{s}) = \rho_1(0) \cdot 5 = \frac{5}{4\pi} \int \int d^2 \Omega_{\hat{n}} \cdot 2 = 10
\]

This means that $\rho(0) = 2$ and

\[
\gamma(0) = 2 d^T_{1ab} d^T_{2ab}
\]

Note that this makes, for instance, the demonstration that the overlap reduction function for coincident, co-aligned IFOs with perpendicular arms is unity, extremely simple. [Just substitute (A8) in for both response tensors.]
III. DEPENDENCE OF THE OVERLAP REDUCTION FUNCTION ON THE ORIENTATION OF A BAR DETECTOR

In this section we consider in detail the form of the overlap reduction function between a bar detector with its long axis along the unit vector \( \hat{u} \) and

1. an IFO with axes along the unit vectors \( \hat{x} \) and \( \hat{y} \)
2. a bar detector with its long axis along the unit vector \( \hat{x} \)
3. a general detector with response tensor \( d_{ab} \)

A. Zero-frequency limit

The relatively simple form (2.13) of \( \gamma(0) \) makes it worthwhile to consider briefly the overlap reduction function in this limit, which can in general be written as

\[
\frac{2\pi f |r_1 - r_2|}{c} \rightarrow 0
\]

and thus also applies to detectors located at the same site.

1. Correlations with an interferometer

For correlations between an IFO and a bar, we use (A8) and (A9) and note that in this case \( d_{ab}^1 \) is already traceless, so

\[
\gamma(0) = 2d_{ab}^1 d_{ab}^2 = \frac{1}{2}[(\hat{x} \cdot \hat{u})^2 - (\hat{y} \cdot \hat{u})^2]
\]

For the case where the detectors lie in the same plane, the IFO’s arms are perpendicular, and the bar makes an angle of \( \theta \) with the IFO’s “x arm” and \( \frac{\pi}{2} - \theta \) with its “y arm”, so that

\[
\hat{x} \cdot \hat{u} = \cos \theta
\]

\[
\hat{y} \cdot \hat{u} = \sin \theta
\]

we have the familiar result that

\[
\gamma(0) = \cos 2\theta
\]
2. Correlations with another bar

In the case of correlations between two bar detectors, the response tensors are

\[ d_{1}^{ab} = \hat{x}^{a} \hat{x}^{b} \]  
\[ d_{2}^{ab} = \hat{u}^{a} \hat{u}^{b} \]

so that from (2.13)

\[ \gamma(0) = 2 \left( d_{1}^{ab} d_{2ab} - \frac{1}{3} d_{1a}^{a} d_{2b}^{b} \right) = 2 \left( (\hat{x} \cdot \hat{u})^{2} - \frac{1}{3} \right) = \cos 2 \theta + \frac{1}{3} \]

(3.6)

where \( \theta \) is the angle between the two bars, so that once again \( \hat{x} \cdot \hat{u} = \cos \theta \).

Note that the maximum value of (3.6), which occurs when \( \theta = 0 \), is \( \frac{2}{3} \), as opposed to the maximum of unity for correlations between an IFO and a bar (3.4) or two IFOs. For this reason, the overlap reduction function for two bars is sometimes (see, e.g., [3, 11]) normalized with an additional factor of \( \frac{3}{4} \) relative to (2.1) so that the maximum at zero frequency is zero for any type of detector pair. The normalization used in this paper is preferred, however, for several reasons:

- Including a detector-dependent normalization factor in the definition of \( \gamma(f) \) would mean formulas like (1.3) would have different forms for different types of detector pairs.

- While the maximum value of \( \gamma(0) \) for two bars is \( \frac{2}{3} \) rather than 1, its minimum value is \( -\frac{2}{3} \) rather than \( -1 \) (which is the minimum value for either two IFOs or an IFO and a bar). So in all three cases the amplitude of the orientation-induced modulation is 1.

The latter point can be physically understood in terms of a bar detector being “more omnidirectional” than an IFO. For an IFO, there is one optimal propagation direction for which the GW response is a maximum, namely a wave propagating perpendicular to the IFO plane. Two IFOs with their arms parallel will both respond ideally to waves propagating in this direction. The same is true if we rotate one of the IFOs 90°, except that the complete correlation of the signals has become an anticorrelation, so \( \gamma = -1 \). On the other hand, a bar detector has a one-parameter family of “optimal” propagation directions, all perpendicular to the bar. Two parallel bars share the same family of optimal directions. However, if we rotate one bar 90°, the planes perpendicular to the bars no longer coincide, and there is only a single optimal propagation direction perpendicular to the bars for which they both respond
optimally. So the anticorrelation in the perpendicular arrangement is not as efficient as the correlation in the parallel arrangement, and $|\gamma(0)|$ is smaller for perpendicular bars than for parallel ones.

**B. General form**

Returning to consideration of the overlap reduction function $\gamma(f)$ for general frequencies and detector separations, what interests us here is the dependence of $\gamma(f)$ on the orientation of the bar. We assume that the locations of the two detectors and the geometry of the other detector are fixed. The one variable is the azimuth of the bar, which is conventionally defined as an angle measured clockwise from the local geographic North. If we define unit vectors $\hat{N}$ and $\hat{E}$ pointing North and East, respectively, the orientation vector for a bar with azimuth $\zeta$ is

$$\hat{u} = \hat{N} \cos \zeta + \hat{E} \sin \zeta$$

its response tensor is

$$d_{ab}^{2} = (\hat{N}^a \cos \zeta + \hat{E}^a \sin \zeta)(\hat{N}^b \cos \zeta + \hat{E}^b \sin \zeta) = d_{ab}^{0} + d_{ab}^{C} \cos 2\zeta + d_{ab}^{S} \sin 2\zeta$$

where

$$d_{ab}^{0} = \frac{\hat{N}^a \hat{N}^b + \hat{E}^a \hat{E}^b}{2}$$

$$d_{ab}^{C} = \frac{\hat{N}^a \hat{N}^b - \hat{E}^a \hat{E}^b}{2}$$

$$d_{ab}^{S} = \frac{\hat{N}^a \hat{E}^b + \hat{E}^a \hat{N}^b}{2}$$

This decomposition of the response tensor into a piece independent of the azimuth, plus pieces proportional to the sine and cosine of twice the azimuth, allows us to write the overlap reduction function as

$$\gamma(f) = \gamma_0(f) + \gamma_C(f) \cos 2\zeta + \gamma_S(f) \sin 2\zeta$$

where

$$\gamma_{0,C,S}(f) = d_{1ab} \Gamma_{cd}(\alpha, \hat{s}) d_{0,C,S}^{cd}$$

Given the location of a bar, it is relatively straightforward to work out the components in some convenient Cartesian basis of the unit vectors $\hat{N}$ and $\hat{E}$ at the location of the bar, and
thus construct the tensors $d^{ab}_0$, $d^{ab}_C$, and $d^{ab}_S$. Those can be used, along with the information about the geometry of the other detector and the separation between the two detectors, to construct the coefficients $\gamma_0(f)$, $\gamma_C(f)$, and $\gamma_S(f)$.

One final improvement on the form (3.10) is to define $\gamma_A(f)$ and $\zeta_{\text{max}}(f)$ according to

$$\gamma_C(f) = \gamma_A(f) \cos 2\zeta_{\text{max}}(f)$$
$$\gamma_S(f) = \gamma_A(f) \sin 2\zeta_{\text{max}}(f)$$

so that

$$\gamma(f) = \gamma_0(f) + \gamma_A(f) \cos 2(\zeta - \zeta_{\text{max}}(f))$$

At a given frequency $f$, $\gamma_0(f)$ is the orientation-independent piece of the overlap reduction function, $\gamma_A(f)$ is the amplitude of the orientation-dependent modulation, and $\zeta_{\text{max}}(f)$ is the orientation (modulo $\pi$) for which the overlap reduction function is a maximum. Note that this is not necessarily the optimal alignment for stochastic background observations; if $\gamma_0(f) < 0$ at the frequency of interest, the stochastic sensitivity is maximized by setting the azimuth to $\zeta_{\text{max}}(f) + \frac{\pi}{2}$ (again modulo $\pi$).

C. Examples for real-world detectors

This section contains several applications of (3.13) to pairs of real-world detectors. In each case the \texttt{detgeom} suite of matlab routines [13] was used to calculate the orientation-independent offset $\gamma_0(f)$, the amplitude $\gamma_A(f)$ of the modulation and the azimuth $\zeta_{\text{max}}(f)$ of maximum overlap, as a function of frequency.

The major bar detectors around the world were oriented roughly parallel to one another as part of agreements through the International Gravitational Event Collaboration (IGEC). This orientation is referred to here as “the IGEC orientation”.

Fig. 1 shows the modulation for the ALLEGRO bar detector (Baton Rouge, LA, USA) correlated with the LIGO Livingston interferometer (Livingston, LA, USA). This is the closest pair of detector sites, separated by only 40 km.

Fig. 2 examines the modulation for the AURIGA bar (Legnaro, Italy) correlated with the Virgo interferometer (Cascina, Italy). AURIGA is the closest bar detector to Virgo, separated by 220 km.
FIG. 1: Modulation of the overlap reduction function for the ALLEGRO bar correlated with the LIGO Livingston interferometer. In the plot at left, the dashed line shows the amplitude $\gamma_A(f)$ of the azimuth-dependent oscillation, while the solid line indicates the azimuth-independent component $\gamma_0(f)$. The detector sites are only separated by 40 km, so the amplitude and offset of the modulation change little between 0 Hz and 1000 Hz. The sensitive frequencies for the correlation measurement are near 900 Hz, and the range of overlap reduction function values as the orientation is changed is $-0.90 < \gamma(900 \text{ Hz}) < 0.96$, which makes this pair of detectors well suited to the modulation of stochastic GW response. Likewise, the optimal orientation differs from that determined at zero frequency by only a fraction of a degree. The IGEC orientation, not shown on these axes, is -40, i.e., 40° West of North.

Fig. 3 shows the modulation for the NAUTILUS bar (Frascati, Italy) correlated with the Virgo interferometer. The two sites are separated by 270 km.

The result (3.13) can also be applied to a pair of bar detectors. Fig. 4 shows the modulation for the AURIGA bar detector correlated with the EXPLORER bar (Geneva, Switzerland). The detectors are separated by 460 km. EXPLORER is assumed to be in its actual IGEC orientation of 39° East of North, and the modulation is that associated with the AURIGA azimuth.
FIG. 2: Modulation of the overlap reduction function for the AURIGA bar correlated with the Virgo interferometer. The dashed line on the right-hand plot indicates AURIGA’s IGEC orientation, for reference. The detector sites are separated by 220 km, so the frequency dependence of the overlap reduction function is important. It happens that in the azimuthal modulation \( \gamma_A(f) \) is rather small at the frequencies of the bar’s sensitivity (around 900 Hz). However, the azimuth-independent offset is non-negligible, which means that \( 0.14 < \gamma(900\,\text{Hz}) < 0.22 \) for all orientations. In particular, it is not possible to change the sign of the gravitational-wave response by altering the orientation of a detector at the AURIGA site.

IV. CONCLUSIONS

For stochastic background measurements correlating a resonant bar detector with another GW detector, we have derived several analytical results about the dependence of the overlap reduction function \( \gamma(f) \), and hence the response to an isotropic SGWB, on the bar’s orientation. In particular:

At zero frequency, the overlap reduction function for any pair of detectors is twice the contraction of the traceless parts of the detectors’ response tensors (2.13). For correlations between an interferometer and a bar lying in the same plane, this has a sinusoidal dependence on the angle between the bar and the interferometer’s “x arm” (3.4). For correlations between two bars, there is still a sinusoidal dependence on the angle between the two bars (3.6), but now that modulation is offset by \( \frac{1}{3} \), so that cross-correlation measurements with parallel bars \( \gamma(0) = \frac{4}{3} \) are more efficient than those with perpendicular bars \( \gamma(0) = -\frac{2}{3} \).
FIG. 3: Modulation of the overlap reduction function for the NAUTILUS bar correlated with the Virgo interferometer. The dashed line on the right-hand plot indicates NAUTILUS’s IGEC orientation, for reference. Since the detectors are separated by 270 km, the amplitude $\gamma_A(f)$ of the modulation has its first minimum below 900 Hz, and the range of overlap reduction function values is $-0.18 < \gamma(900 \text{ Hz}) < 0.07$, depending on the bar’s azimuth angle. Note also that while $\zeta_{\text{max}}(900 \text{ Hz}) = 98^\circ$, this is the azimuth for which $\gamma(900 \text{ Hz})$ is a maximum; the maximum of $|\gamma(900 \text{ Hz})|$ is in the perpendicular alignment, an azimuth of $8^\circ$ East of North. Note also that while the actual IGEC azimuth of $44^\circ$ is $36^\circ$ away from this optimal orientation, this is not as close to a “null” alignment as it seems because of the offset $\gamma_A(900 \text{ Hz}) = -0.06$, which makes $\gamma(900 \text{ Hz}) = -0.10$ for the IGEC orientation.

This can be understood, as explained in Sec. IIIA.2, in terms of the distribution of optimal propagation directions for bar detectors.

At higher frequencies, we have confirmed the empirical result seen in [5] of a sinusoidal azimuthal modulation of the overlap reduction function, generally offset from zero mean [5.13]. We have also verified that the modulation has a period of $180^\circ$ with no higher-order moments, and give explicit expressions for the amplitude $\gamma_A(f)$, offset, $\gamma_0(f)$ and phase $\zeta_{\text{max}}(f)$ of the azimuthal modulation, in terms of geometrical quantities such as the detector response tensor and the unit vectors associated with the bar detector’s location.

Finally, we have illustrated these results in Section III.C by applying them to several pairs of real-world detectors. LLO-ALLEGRO has the best observing geometry and the greatest opportunity for modulation, with $\gamma(900 \text{ Hz})$ varying between $-0.90$ and $0.96$ with
FIG. 4: Modulation of the overlap reduction function for the AURIGA bar correlated with the EXPLORER bar. EXPLORER is assumed to be in its actual IGEC orientation of $39^{\circ}$ East of North. Note that, as discussed in Sec. III A 2, the offset of the modulation at zero frequency is $1/3$ rather than zero. Note also that at zero frequency, the azimuth $\zeta_{\text{max}}(0)$ of maximum overlap is nearly equal to the actual IGEC azimuth, which is to be expected since in that orientation the bars are nearly parallel.

azimuth. The AURIGA bar has a reasonable observing geometry with Virgo, but little opportunity for modulation if it were rotated, with $\gamma(900 \, \text{Hz})$ ranging from 0.14 to 0.22, while NAUTILUS and Virgo have a slightly less favorable geometry on average, but greater potential modulation, with $\gamma(900 \, \text{Hz})$ between $-0.18$ and $0.07$.

APPENDIX A: CONVENTIONS AND DEFINITIONS

Lowercase Latin letters \((a, b, c, \ldots)\) will represent spatial indices ranging from 1 to 3, which can be raised or lowered with the Kronecker delta \(\delta_{ab}\). The Einstein summation convention will be used for these indices.

The propagation direction of a plane wave is defined by a unit vector \(\hat{n}\); given such a unit vector, one can choose an arbitrary unit vector \(\hat{\ell}\) perpendicular to \(\hat{n}\) and then define \(\hat{m} = \hat{n} \times \hat{\ell}\) so that \(\{\hat{\ell}, \hat{m}, \hat{n}\}\) form a right-handed orthonormal basis. Given such a basis, it is conventional to define transverse, traceless polarization tensors

\[
\begin{align*}
\epsilon^{ab}_{\pm}(\hat{n}) &= \ell^a \ell^b - m^a m^b \quad (A1a) \\
\epsilon^{ab}_{\times}(\hat{n}) &= \ell^a m^b + m^a \ell^b \\ 
\end{align*}
\]

Note that while these tensors span the space of traceless, symmetric tensors transverse to \(\hat{n}\), they are not orthonormal under the obvious choice of inner product on that space, since

\[
\epsilon_{Aab}(\hat{n}) \epsilon_{A'cd}(\hat{n}) = 2 \delta_{AA'} \quad (A2)
\]

where \(A\) and \(A'\) are polarization indices, which can take on the values + and \(\times\).

It is useful to define the projector onto traceless, symmetric tensors transverse to the unit vector \(\hat{n}\):

\[
P^{TT\hat{n}ab}_{cd} = \frac{1}{2} \sum_{A=+,-,\times} \epsilon^{ab}_{A}(\hat{n}) \epsilon_{Acd}(\hat{n}) \\
\]

The factor of 1/2 is needed to make this a projector, because of the factor of two appearing in (A2). Note that while the polarization basis tensors depend on the (arbitrary) choice of \(\hat{\ell}\), the projector only depends on the unit vector \(\hat{n}\). Note also that, because it is a projector onto a two-dimensional subspace,

\[
P^{TT\hat{n}ab}_{ab} = 2 \\
\]

Another useful projector is that onto traceless, symmetric tensors:

\[
P^{T_{ab}}_{cd} = \delta^a_{(c} \delta^b_{d)} - \frac{1}{3} \epsilon^{ab}_{cd} \\
\]

Note that because this is a projector onto a five-dimensional subspace,

\[
P^{T_{ab}}_{ab} = 5 \\
\]
Finally, we note here the forms of the response tensors for interferometric and resonant bar detectors. The response of a gravitational wave detector to a GW-induced metric perturbation $h_{ab}(t, \vec{r})$ is

$$h(t) = h_{ab}(t, \vec{r}_{\text{det}}) d^{ab}$$

(A7)

where $\vec{r}_{\text{det}}$ is the spatial location of the detector and $d^{ab}$ is a symmetric tensor describing the detector geometry. The response tensor for an IFO with arms along the (not necessarily perpendicular) unit vectors $\hat{x}$ and $\hat{y}$ is

$$d^{ab}_{(\text{ifo})} = \frac{1}{2}(\hat{x}^a \hat{x}^b - \hat{y}^a \hat{y}^b)$$

(A8)

while that for a cylindrical resonant bar detector with its long axis along the unit vector $\hat{u}$ is

$$d^{ab}_{(\text{bar})} = \hat{u}^a \hat{u}^b$$

(A9)

Note that we choose not to make the response tensor for the bar detector explicitly traceless. It is often useful to work with the traceless piece of a response tensor

$$d^{T ab} = P^{T cd} d^{cd} = d^{ab} - \frac{1}{3} \delta^{ab} d^{cc}$$

(A10)

which for a bar is

$$d^{T ab}_{(\text{bar})} = \hat{u}^a \hat{u}^b - \frac{1}{3} \delta^{ab}$$

(A11)

($d^{ab}_{(\text{ifo})}$ is, of course, already traceless)

Finally, a standard pair of quantities used in describing GW detector response is a detector’s beam pattern functions for the two polarization states, defined by

$$F_A(\hat{n}) = d^{ab} e_{A,ab}(\hat{n})$$

(A12)

**APPENDIX B: DERIVATION OF THE COEFFICIENTS IN THE OVERLAP REDUCTION FUNCTION**

In this appendix we find the values of the coefficients $\rho_1(\alpha)$, $\rho_2(\alpha)$, and $\rho_3(\alpha)$ appearing in

$$\Gamma^{ab}_{cd}(\alpha, \hat{s}) = \frac{5}{4\pi} \int d^2 \Omega_{\hat{n}} P^{T T \hat{n}}_{cd} e^{i\alpha \hat{n} \cdot \hat{s}} = \sum_{n=1}^{3} \rho_n(\alpha) T^{n,ab}_{n,cd}$$

(B1)
We do this by contracting each of the \( \{ T_{n,cd} \} \) in turn with \( \Gamma_{ab}(\alpha, \hat{s}) \):

\[
T_{1,cd}^{ab} \Gamma_{cd}(\alpha, \hat{s}) = \frac{5}{4\pi} \int d^2 \Omega_{\hat{n}} P^{TT_{nab}} e^{i\alpha \cdot \hat{n} \cdot \hat{s}}
\]

(B2a)

\[
T_{2,cd}^{ab} \Gamma_{cd}(\alpha, \hat{s}) = \frac{5}{4\pi} \int d^2 \Omega_{\hat{n}} P^{TT_{nab}} e^{i\alpha \cdot \hat{n} \cdot \hat{s}}
\]

(B2b)

\[
T_{3,cd}^{ab} \Gamma_{cd}(\alpha, \hat{s}) = \frac{5}{4\pi} \int d^2 \Omega_{\hat{n}} P^{TT_{nab}} e^{i\alpha \cdot \hat{n} \cdot \hat{s}}
\]

(B2c)

The three contractions appearing in the integrands can be written:

\[
P^{TT_{nab}}_{ab} = 2
\]

(B3a)

\[
P^{TT_{nab}}_{ac} = 1 - (\hat{n} \cdot \hat{s})^2
\]

(B3b)

\[
P^{TT_{nab}}_{cd} \hat{s}_a \hat{s}_b \hat{s}_c \hat{s}_d = \frac{1}{2} \left[ (e^{ab}(\hat{n}) \hat{s}_a \hat{s}_b)^2 + (e^{ab}(\hat{n}) \hat{s}_a \hat{s}_b)^2 \right] = \frac{1}{2} \left[ 1 - (\hat{n} \cdot \hat{s})^2 \right] ^2
\]

(B3c)

Where we have used

\[
P^{TT_{nab}}_{ac} = \frac{1}{2} \left[ e^{ab}(\hat{n}) e_{ac}(\hat{n}) + e_{ac}(\hat{n}) e^{ab}(\hat{n}) \right] = \ell^a \ell_c + m^b m_c = \delta^b_c - n^a n_c
\]

(B4)

and, defining a spherical coordinate system such that

\[
\hat{s} = \sin \theta \cos \phi \hat{\ell} + \sin \theta \sin \phi \hat{m} + \cos \theta \hat{n},
\]

(B5)

\[
e_{+}(\hat{n}) \hat{s}_a \hat{s}_b = (\hat{\ell} \cdot \hat{s})^2 - (\hat{m} \cdot \hat{s})^2 = \sin^2 \theta \left( \cos^2 \phi - \sin^2 \phi \right) = \sin^2 \theta \cos 2\phi
\]

(B6)

and

\[
e_{-}(\hat{n}) \hat{s}_a \hat{s}_b = \hat{s} \cdot \hat{s} = 2(\hat{\ell} \cdot \hat{s})(\hat{m} \cdot \hat{s}) = 2 \sin^2 \theta \cos \phi \sin \phi = \sin^2 \theta \sin 2\phi
\]

(B7)

This makes the contractions

\[
T_{1,cd}^{ab} \Gamma_{cd}(\alpha, \hat{s}) = 5 \int_{-1}^{1} e^{i\alpha \mu} d\mu = 10 \frac{\sin \alpha}{\alpha} = 10 j_0(\alpha)
\]

(B8a)

\[
T_{2,cd}^{ab} \Gamma_{cd}(\alpha, \hat{s}) = \frac{5}{2} \int_{-1}^{1} (1 - \mu^2) e^{i\alpha \mu} d\mu = 5 \left( -\frac{2 \cos \alpha}{\alpha^2} + \frac{2 \sin \alpha}{\alpha^3} \right) = \frac{10 j_1(\alpha)}{\alpha}
\]

(B8b)

\[
T_{3,cd}^{ab} \Gamma_{cd}(\alpha, \hat{s}) = \frac{5}{4} \int_{-1}^{1} (1 - 2 \mu^2 + \mu^4) e^{i\alpha \mu} d\mu = 5 \left( -\frac{4 \sin \alpha}{\alpha^3} - \frac{12 \cos \alpha}{\alpha^4} + \frac{12 \sin \alpha}{\alpha^5} \right) = \frac{20 j_2(\alpha)}{\alpha^2}
\]

(B8c)

To work out the contractions of the \( \{ T_{n,cd} \} \) with the right-hand side of (B1), we just need to contract each of them with the others. We demonstrate the calculation explicitly here in our notation:

\[
T_{1,cd}^{ab} T_{1,cd}^{ab} = P^{T_{ab}}_{cd} = 5
\]

(B9)
To get
\[ T_{1cd}^a T_{2ab}^b = P_{ac}^a \delta^b_b \delta^c_c \]  
(B10)
we note that
\[ P_{ac}^a = \frac{1}{2} \delta^a_a + \frac{1}{2} \delta^a_c \delta^c_a - \frac{1}{3} \delta^a_b \delta^b_a = \left( \frac{3}{2} + \frac{1}{2} - \frac{1}{3} \right) \delta^b_a \]  
(B11)
so
\[ T_{1cd}^a T_{2ab}^b = \frac{5}{3} \]  
(B12)
Next
\[ T_{1cd}^a T_{3ab}^d = P_{cd}^a \delta^b_b \delta^c_c \delta^d_d = 1 - \frac{1}{3} = \frac{2}{3} \]  
(B13)
To work out
\[ T_{2cd}^a T_{2ab}^d = P_{ef}^a \delta^b_b \delta^c_c \delta^d_d P_{ac}^a \]  
(B14)
We note that
\[ P_{ef}^a \delta^b_b \delta^c_c \delta^d_d = \frac{1}{2} \delta^a_e + \frac{1}{2} \delta^a_f \delta^f_e - \frac{1}{3} \delta^a_e \delta^e_a = \frac{1}{2} \left( \delta^a_e + \frac{1}{3} \delta^a_e \right) \]  
(B15)
so
\[ T_{2cd}^a T_{2ab}^d = \frac{1}{4} \left( \delta^a_e + \frac{1}{3} \delta^a_e \right) \left( \delta^c_f + \frac{1}{3} \delta^c_f \right) = \frac{1}{4} \left( 3 + \frac{1}{3} + \frac{1}{3} + \frac{1}{9} \right) = \frac{17}{18} \]  
(B16)
To calculate
\[ T_{2cd}^a T_{3ab}^d = \delta^a_a \delta^b_b \delta^c_c \delta^d_d P_{ef}^a \delta^b_b \delta^c_c \delta^d_d P_{ac}^a \]  
(B17)
we note that
\[ \delta^a_a \delta^b_b \delta^c_c \delta^d_d P_{ef}^a \delta^b_b \delta^c_c \delta^d_d = \left( \delta^a_e \delta^b_f - \frac{1}{3} \delta^f_e \right) \delta_f = \frac{2}{3} \delta^a_e \]  
(B18)
so
\[ T_{2cd}^a T_{3ab}^d = \frac{4}{9} \]  
(B19)
Finally,
\[ T_{3cd}^a T_{3ab}^d = \left( \delta^a_a \delta^b_b - \frac{1}{3} \delta^a_b \right) \left( \delta^a_a \delta^b_b - \frac{1}{3} \delta^a_b \right) = \left( 1 - \frac{1}{3} + \frac{3}{9} \right)^2 \]  
(B20)
We can summarize these results as
\[
\begin{pmatrix}
T_{1cd}^a \\
T_{2cd}^a \\
T_{3cd}^a
\end{pmatrix} \begin{pmatrix}
T_{1cd}^b \\
T_{2cd}^b \\
T_{3cd}^b
\end{pmatrix} = \begin{pmatrix}
5 & 5/3 & 2/3 \\
5/3 & 17/18 & 4/9 \\
2/3 & 4/9 & 4/9
\end{pmatrix}
\]  
(B21)
which we can use, along with

\[
\Gamma_{ab}^{cd}(\alpha, \hat{s}) = \begin{pmatrix}
T_{1cd}^{ab} & T_{2cd}^{ab} & T_{3cd}^{ab}
\end{pmatrix}
\begin{pmatrix}
\rho_1(\alpha) \\
\rho_2(\alpha) \\
\rho_3(\alpha)
\end{pmatrix}
\]  \hspace{1cm} (B22)

to combine the three sets of contractions in the matrix equation

\[
\begin{pmatrix}
10j_0(\alpha) \\
10\frac{j_1(\alpha)}{\alpha} \\
20\frac{j_2(\alpha)}{\alpha^2}
\end{pmatrix}
= 
\begin{pmatrix}
T_{1cd}^{ab} \\
T_{2cd}^{ab} \\
T_{3cd}^{ab}
\end{pmatrix}
\Gamma_{ab}^{cd}(\alpha, \hat{s})
= 
\begin{pmatrix}
5 & 5/3 & 2/3 \\
5/3 & 17/18 & 4/9 \\
2/3 & 4/9 & 4/9
\end{pmatrix}
\begin{pmatrix}
\rho_1(\alpha) \\
\rho_2(\alpha) \\
\rho_3(\alpha)
\end{pmatrix}
\]  \hspace{1cm} (B23)

Inverting the matrix gives

\[
\begin{pmatrix}
\rho_1(\alpha) \\
\rho_2(\alpha) \\
\rho_3(\alpha)
\end{pmatrix}
= 
\begin{pmatrix}
1/2 & -1 & 1/2 \\
-1 & 4 & -5/2 \\
1/4 & -5/2 & 35/8
\end{pmatrix}
\begin{pmatrix}
10j_0(\alpha) \\
10\frac{j_1(\alpha)}{\alpha} \\
20\frac{j_2(\alpha)}{\alpha^2}
\end{pmatrix}
= 
\begin{pmatrix}
5 & -10 & 5 \\
-10 & 40 & 50 \\
5/2 & -25 & 175/2
\end{pmatrix}
\begin{pmatrix}
\frac{j_0(\alpha)}{\alpha} \\
\frac{j_1(\alpha)}{\alpha^2} \\
\frac{j_2(\alpha)}{\alpha^3}
\end{pmatrix}
\]  \hspace{1cm} (B24)

which are the standard coefficients in the expansion (2.9)
